University of Belgrade – Faculty of Mechanical Engineering, Serbia

The paper presents results of theoretical numerical research dealing with CO and NOx emission performed in the process of optimization of the performance of low-power atmospheric burners.

The theoretical part of this paper, whose main goals were better understanding of the complex issues of methodology and establishment of performance prediction and optimization of low-power atmospheric gas burner included numerical variation of independent parameters, such as burner geometry, the coefficients of primary and secondary air and different gaseous fuels including biogas.

The findings of theoretically obtained performance prediction and optimization of atmospheric burners were experimentally investigated in purpose built test rigs for a number of variable parameters. The obtained results fully justified the proposed models of performance prediction and burner optimization.

Key words: combustion, atmospheric burner, optimization, performance.

1. Introduction

In this paper the results of theoretical research performed within the process of optimizing the performance of low power atmospheric burners are presented. In the theoretical phase, the main goals were to better understand the complex problems of atmospheric burner operation and to form a methodology for predicting the performance and optimization of low-power atmospheric burners, introducing burner geometry, primary and secondary air coefficients, as well as gaseous fuel types including pure methane \( \text{CH}_4 \) (99.73 purity) [1] and biogas. Although this combustion system has a long tradition, it is quite surprising that the issue of atmospheric burners is relatively modestly represented in the available literature. In this respect, the authors had no opportunity to compare their work with some similar research of this issue in virtually all its aspects. The main objectives to be achieved by the construction and the development of modern atmospheric burners include the following categories: the stability of the work, the dynamic range of operation, emissions, lifetime of a burner, the degree of usefulness of the gas devices (consumers) in which the burner is to be installed, and the price of the burner. Design of a flexible burner incorporates a proper procedure and implementation of CFD codes but first of all understanding of chemical reactions that take place, how they affect the flame behaviour and how the flame interacts with the flow field.

The combination of commercially available chemical reactions, flow codes and reduced chemical kinetics mechanisms with semi empirical models of low heat value fuels combustion were needed to
be developed to enable reliable and fast numerical analysis of practical burners when more parameters are varied. Sub-task was defined as a fundamental research of chemical reaction mechanisms, modelling of emissions and flame structure in premixed combustion systems.

2. Modeling of premixed flame systems

Forming of the mathematical model or modeling of the combustion process, in this case consists of a fundamental part that includes: the phenomenology of chemical reactions and flame propagation, then variables that affect these phenomena (excess air coefficient, type of fuel, etc.). In premixed combustion, the fuel and oxidizer are already mixed at the molecular level before the fuel mixture is ignited. Combustion with a premixed flame is more complex for modeling than combustion with an unpreamixed flame. Appropriate restrictions are set along with the goal. [2] The reason for this is that combustion with a premixed flame takes place in a thin layer whose geometry is affected by turbulence. In subsonic flows, the flame front propagation is determined by the laminar flame front propagation and turbulent vortices.[11,15] The laminar flame front propagation is determined by the complex effect of the simultaneous action of chemical reactions and the phenomenon of heat transfer and propagation with flow right next to reactants that have yet to enter the thermochemical reaction.[3] The effect of turbulence is reduced to the contraction and expansion of the flame in the laminar flame zone, increasing the laminar flame zone and, consequently, the effective flame front propagation.[4,16] Large vortices tend to deform the laminar flame zone, while small vortices, if smaller than the thickness of the laminar flame, penetrate the laminar flame zone and intend to modify the laminar flame structure.[5]

3. Modeling of chemical reactions, emissions of combustion products and flame structure

3.1. The goal of modeling

Flame structure and emissions were modeled using the CHEMKIN program (Reaction Design, California USA). This program contains various models of chemical reactors. The one corresponding to the burner simulation with a laminar methane/air premixed flame was selected. This one-dimensional model of the reactor allows the calculation of: temperature profile, concentrations of the main components, intermediate elements and then flame propagation ratio as a function of distance. The flame structure and burner emissions with a laminar premixed methane/air flame [12] were calculated at an initial temperature of 298 K and at a pressure of 1.013 x 10^5 Pa. [6] The calculation was performed in the domain of 10 cm, which is significantly more than the thickness of the flame.[9] The coefficient of primary excess air \( \lambda' \) varied from 1.0 to 1.7. This data represents the input parameters of the executed calculation. The results of this numerical test are illustrated in Pictures 1 to 10:
1. Temperature profile for $\lambda' = 1.0$

2. Concentration (O, CH, NO, NO$_2$) for $\lambda'=1.0$

3. Concentration (O$_2$, H$_2$O, CH$_4$, CO, CO$_2$) for $\lambda'= 1.0$

4. Concentration (H$_2$O, H, OH) for $\lambda'= 1.0$

5. Concentration (HO$_2$, H$_2$O$_2$) for $\lambda'= 1.0$

6. Temperature profile for $\lambda'= 1.7$
Based on the obtained results, it can be seen that the maximum values of the flame temperature decrease from 2080 K to 1700 K with an increase in the coefficient of excess primary air $\lambda'$ from 1.0 to 1.7. At the same time, the temperature profile gradients also decrease.

Combustion product concentration profiles also change with $\lambda'$. The maximum molar proportions of atomic oxygen (O) decrease from 0.34% to 0.09% with increasing $\lambda'$. The peaks are moved by approximately 0.1 to 0.2 cm above the burner with an increase in $\lambda'$ of 1.0 to 1.7. Emissions of NOX and CH radicals, as a function of distance, are shown in pictures 2 and 7. Nitrogen oxides almost
entirely consist of NO which reaches a maximum for $\lambda' = 1$ and decreases to a minimum value for $\lambda' = 1.7$. The NO$_2$ concentration is negligible. A summary of the change in NO$_X$ is given in Picture 12.

The maximum values of CO concentration are in the flame zone. In the post-flame zone, CO is reduced to a level of about 2%, in the case of stoichiometric combustion, and to less than 1% for $\lambda' = 1.1$. With a further increase in $\lambda'$, the value of CO concentration decreases drastically. A summary of the change in CO is given in Picture 13. As a result of a smaller amount of fuel in the fuel mixture with increasing $\lambda'$ the final concentrations of CO$_2$ and H$_2$O decrease. CO$_2$ and H$_2$O concentrations decrease because the area with the higher temperature moves higher above the burner. HO$_2$ and H$_2$O$_2$ are formed in the combustion zone and completely degrade after the combustion process is completed. The laminar flame front propagation rate as a function of the coefficient of primary excess air $\lambda'$ is shown in Picture 14.

Laminar flame front propagation rate, which is shown in Picture 16, as a function of the reciprocal value of the coefficient of excess air, i.e. size, which in Anglo-Saxon terminology is called Equivalance ratio, shows slightly lower values for stoichiometric combustion conditions ($\lambda' = 1$) and slightly higher values for $\lambda' = 1.7$.

4.1. Flame structure and premixed flame emissions for Serbian natural gas

Calculations related to the structure of premixed flame and emission in burners with stable operation, during combustion of the mixture Serbian natural gas/air, were performed at an initial temperature of 298 K, at a pressure of 1.013 x 10⁵ Pa, where, as in the previous case, the coefficient of excess primary air λ’ is varied from 1.0 to 1.7. The composition of Serbian natural gas is given in the table 1:

4.2. Flame structure and emissions in premixed biogas flames

Biogas is a mixture of methane CH$_4$ and carbon dioxide CO$_2$ in a ratio of 60% to 40% respectively. The test results presented in this paper were obtained for a lean biogas/air mixture, and relate to flame front velocity, temperature profile, emission, and flame structure.[10,19] The flame structure and combustion emissions [17], with a laminar premixed flame, of a lean biogas/air mixture [14] at an initial temperature of 298 K and a pressure of 1.013 x 10$^5$ Pa were calculated. The calculation was performed in the domain of 10 cm, which is significantly more than the thickness of the flame. The coefficient of excess primary air $\lambda'$ varied from 1.0 to 1.5. The obtained results of this numerical test are shown in the following pictures:
From the presented results (Pictures 19 to 24) for biogas, it can be seen that the laminar flame front propagation ratio is slightly lower in biogas than in pure CH₄, also NOₓ emissions are lower while CO emissions are significantly higher in biogas than in CH₄. The flame temperature in biogas does not change much in relation to the flame temperature in CH₄.

5. Methodology

Methodology of numerical optimization of the performance of an atmospheric burner basically consists of three tasks: forming an optimization model, application of the proposed optimization model on a specific burner model and validation of the proposed optimization model. Forming of the optimization model implies defining of the mathematical model which is than used for numerical analysis and the burner optimization. Research within the optimization of the atmospheric gas burner basically consists of two parts: determining the performance of burners in open space and determining the performance of the burner integrated in the chosen combustion chamber. In order to systematize and facilitate monitoring, this paper will present only the test details relevant to the optimization process. Based on the set requirements, in the project task, the preliminary construction of the burner was performed. The design of the burner depends on the required performance, the choice of burner construction and the type of fuel that the burner will use. Parameters such as burner design characteristics, burner thermal power, type of fuel, type of material from which the burner is made, etc., have a direct impact on the performance and stability of the burner, whose numerical consideration leads to final conclusions and adoption of burner design. According to the adopted design solution of the burner, the numerical testing of the burner in different design conditions and operating modes is performed. The obtained results have an impact on the changes in the adopted design solutions, which are applied in the further evolutionary development of the burners, after which a re-experimental examination of the new adopted solutions will be tested.

6. Burner model

The development of the burner model assumes the definition of the geometry of all the elements of which the burner is made and their functional connection into the working unit with the appropriate required characteristics.
6.1. **Modeling the formation of a mixture of fuel and air**

This part of the paper will explain the basic principles of calculating the coefficient of excess primary air depending on the aerodynamic properties of the burner and the combustion chamber of the gas device in which the considered burner is installed. The main task is to consider the influence of optimized quantities on the stability (combustion) of burners, efficiency, emission of pollutants (CO and NO\textsubscript{X}) and the dynamic range of operation. The following were taken into account:
- Detailed burner geometry including fuel injector (nozzle, ejector, diffuser, burner body, flame ports surface).
- Working conditions (flow of fuel and air mixture, dynamic scope of work, type and composition of fuel, coefficient of excess primary air).
- Interaction between geometry and aerodynamics.

6.2. **Burner model**

For practical application when dimensioning the burner elements, we move on to a simplified one-dimensional consideration of the internal aerodynamics of the gas burner-combustion system. The construction scheme of the ALFA 9 burner gas heater system is given in Figure 1.

![Figure 1. Optimized burner in the combustion chamber of the gas heater ALFA 9](image)

6.3. **Influential parameters**

The parameters that affect the achievement of the above goals are: work pressure, type of fuel, nozzle selection, distance of the nozzle from the mixer, type of mixer, surface of flame ports surface. These parameters in a complex way affect the performance of the burner.

Considering that atmospheric burners are mainly intended for households and that their thermal power ranges from 8 to 12 kW. Atmospheric burner manufactured by BCT from Netherlands was selected. The initial elements of the burner geometry are defined by the initial quantities. The details are: thermal power of the burner 10.2 kW.

In order to achieve the property of multi-fuel, various gaseous fuels were used during the test: commercial mixture of propane and butane (LPG), Serbian natural gas, biogas. The dynamic range of the burner should be 1: 3. The NO\textsubscript{X} and CO emission limit values are 50 mg / kWh, respectively.
The propagation of the flame front is modeled by solving the transport equation in which the process variable appears. Namely, the variable that appears in the equation, denoted by, is called the process variable and represents the total amount of combustion products expressed in mass percentages, averaged with the equilibrium mass fractions of combustion products. This equation has the following form:

$$\frac{\partial}{\partial t}\left(\rho \cdot c\right) + \nabla \cdot \left(\rho \cdot \vec{v} \cdot c\right) = \nabla \cdot \left(\frac{\mu}{S_{C_i}} \cdot \nabla \cdot c\right) + \rho \cdot S_{c},$$  \hspace{1cm} (1)

Process variable is defined as the normalized sum of combustion products:

$$c = \frac{\sum_{i=1}^{n} Y_i}{\sum_{i=1}^{n} Y_{i,eq}},$$  \hspace{1cm} (2)

By definition, $c = 0$ in the non-combustion zone, in the zone where the combustion of the fuel mixture is completed: $c = 0$ – unburned fuel mixture, $c = 1$ – burnt fuel mixture.

The value of the process variable $c$ is given as a boundary condition for all input quantities in the considered system. Usually the value of $c$ is specified either as 0 (unburned fuel mixture) or as 1 (burned fuel mixture).

The mean value of the reaction in equation (1), is given as:

$$\rho \cdot S_{c} = \rho_{u} \cdot U_{f} \cdot |\nabla \cdot c|,$$  \hspace{1cm} (3)

Based on the semi-empirical approach and equation (1), the characteristics of the optimized burner were calculated in order to predict its performance and their harmonization with the required set values at the beginning of the work. This calculation included the coefficient of primary excess air as a function of: thermal power of the burner, nozzle diameter, the diameter of the Venturi tube neck, burner flame ports surfaces and pressure drop in the burner. Methane $\text{CH}_4$, biogas with composition of 60% $\text{CH}_4$ and 40% $\text{CO}_2$ [13] and propane $\text{C}_3\text{H}_8$ were used as base fuel in the calculation.

6.4. Coefficient of primary excess air $\lambda'$

The resistance to the flow through the burner affects the value of the coefficient of primary excess air $\lambda'$. Based on the calculation presented in previous chapter, pictures 25, 26 and 27 are obtained, which show the relationship between the coefficient of friction determined on the basis of the normal flow rate through the flame ports and the coefficient of primary excess air $\lambda'$ for different types of gaseous fuel ($\text{CH}_4$, biogas: 40% $\text{CO}_2$ + 60% and $\text{C}_3\text{H}_8$). On picture 28 dependence of the coefficient of primary excess air on the changes of the flame ports surface at a constant burner heat output of 10.2 kW, for the different fuel types.[18]
7. Analysis of the presented results

Based on the obtained results, the following analysis was performed. Pictures 29 and 30 show the dependence of the average mixture flow rate through the flame ports $u_{AV,DIS}$, the flame front propagation rate $u_{FP}$, as well as the change in the excess air coefficient $\lambda$ depending on the change in the flame ports surface of the burner $A_{pl} / A_{pl0}$. Two cases were considered: operating mode at maximum power $P = 10.2$ kW and operating mode at three times lower power $P = 3.4$ kW, which corresponds to a dynamic burner operating range of 1:3.

Picture 29. Dependence of $u_{AV,DIS}$, $u_{FP}$, $\lambda$, CO and NOX emissions on $A_{pl} / A_{pl0}$ for CH$_4$ at power of $P = 3.4$ kW

Picture 30. Dependence of $u_{AV,DIS}$, $u_{FP}$, $\lambda$, CO and NOX emissions on $A_{pl} / A_{pl0}$ for CH$_4$ at power of $P = 10.2$ kW
It can be seen, in picture 29, that at a power of 3.4 kW (fuel: 100% CH₄) the average flow rates of fuel /air mixture through the flame ports $u_{AV,DIS}$ and flame front propagation rate $u_{FP}$ intersect at the value $A_{pl}/A_{p0} = 1.033$. Until $A_{pl}/A_{p0} = 1.033$ we can see that $u_{FP} > u_{AV,DIS}$ and flame retraction phenomena occurs (Flash back), from $A_{pl}/A_{p0} = 1.033$ is $u_{FP} < u_{AV,DIS}$ and we have a lifting of the flame, and with further increase $A_{pl}/A_{p0}$ ($A_{pl}/A_{p0} > 1.6$) we would have an increasing difference between $u_{FP}$ and $u_{AV,DIS}$, so at one point ($u_{FP} < u_{AV,DIS}$) the flame would be a blown away (blow off).

On picture 30, it can be seen that at a power of 10.2 kW (fuel: 100% CH₄) the average flow rates of fuel /air mixture through the flame openings in the $u_{AV,DIS}$ and the flame front propagation rate $u_{FP}$ do not intersect, but all the time $u_{FP} < u_{AV,DIS}$. Until $u_{FP} < u_{AV,DIS}$, which means that we have a lifted flame all the time, and with the further increase $A_{pl}/A_{p0}$ ($A_{pl}/A_{p0} > 1.6$) we would have an increasing difference between $u_{FP}$ and $u_{AV,DIS}$, so at one point ($u_{FP} < u_{AV,DIS}$) the flame would be a blown away (blow off).

The same consideration was applied when using biogas with a composition of 60% CH₄ and 40% CO₂. The dependence of the average flow rate of fuel /air mixture through the flame openings $u_{AV,DIS}$, the flame front propagation rate $u_{FP}$, as well as the change in the coefficient of excess air $\lambda$ depending on the change in the flame ports surface of the burner $A_{pl}/A_{p0}$ are shown in pictures 31 and 32.

![Picture 31](image1.png)

Picture 31. Dependence of $u_{AV,DIS}$, $u_{FP}$, $\lambda$, CO and NOₓ emissions on $A_{pl}/A_{p0}$ for biogas at power from $P = 3.4$ kW

![Picture 32](image2.png)

Picture 32. Dependence of $u_{AV,DIS}$, $u_{FP}$, $\lambda$, CO and NOₓ emissions on $A_{pl}/A_{p0}$ for biogas at power from $P = 10.2$ kW

It can be seen, on picture 31, that at a power of 3.4 kW (fuel: biogas composition of 60% CH₄ and 40% CO₂) the average flow rates of fuel /air mixture through the flame ports $u_{AV,DIS}$ and the flame front propagation rates $u_{FP}$ do not intersect, but all the time $u_{FP} < u_{AV,DIS}$, which means that we have a turbulent flame lifted all the time. It is also visible that at this power both curves with increasing $A_{pl}/A_{p0}$ keep almost the same trend so there will be no flame blow off phenomenon.

Also on picture 32, it can be seen that at a power of 10.2 kW (biogas fuel composition 60% CH₄ and 40% CO₂), the average flow rates of fuel /air mixture through the flame ports $u_{AV,DIS}$ the flame front propagation rates $u_{FP}$ do not intersect but all the time ther is $u_{FP} < u_{AV,DIS}$, although there is a larger difference in the values of $u_{AV,DIS}$ and $u_{FP}$ in relation to the power of 3.4 kW, which means that we have a turbulent flame lifted all the time, it is also visible that at this power both curves with the increase of $A_{pl}/A_{p0}$ keep almost the same trend so that the blow off of flame will not occur.
8. Conclusion

The influence of the mentioned elements on the stability of burner operation and NO$_X$ and CO emissions was analyzed. Based on these analyzes, an optimization method has been developed whose functions are to increase the stability of the optimized atmospheric burner and meet the limit values of NO$_X$ and CO emissions. Based on performed theoretical analyses, a method for optimizing the performance of low-power multifuel atmospheric burners has been formed and numerical research had been performed. The obtained results of this numerical research were used for construction of the prototype burner. Based on these calculations, reconstructive improvements are made to the burner prototype and the first stage of burner evolution is obtained. In addition experimental verification of the proposed burner prototype were performed in order to confirm the needed performances of this burner. This optimization method fully confirmed the quality of the proposed performance optimization methodology in terms of stability, dynamic range and emissions, which is also contributing to increase of the energy efficiency of low power gas appliances and meet environmental requirements, ie sustainable development.

Procedure can be repeated as many times as necessary to obtain the final prototype of the burner that has the required performance, defined in the optimization task and confirmed on the test bench and in the gas appliance for which the burner is optimized. Theoretical optimization of the burner was performed by this procedure. The extent to which the theoretical approach provided a methodology for optimizing atmospheric burners can be confirmed by appropriate experimental research.

Nomenclature

- $\lambda'$ Coefficient of primary excess air, -
- $L$ Distance, cm
- $A_{p0}$ Initial area of the flame ports surface, mm$^2$
- $A_{pl}$ Area of the flame ports surface, mm$^2$
- $c$ Process variable size of the observed chemical reaction, -
- $Sc_t$ Turbulent Schmidt number, -
- $Sc$ Member of the equation that describes the formation of a process variable, s$^{-1}$
- $n$ Number of combustion products, -
- $Y_i$ Mass fraction of i-th combustion product, -
- $Y_{i,eq}$ Equilibrium mass fraction of the i-th combustion product, -
- $\rho_u$ Density of unburned fuel mixture, kg/m$^3$
- $U_t$ Turbulent flame velocity, m/s
- $\mu$ Jet contraction coefficient, -
- $d_{ml}$ Nozzle diameter, mm
- $Hd$ Thermal power of the fuel, kJ/kg
- $\Delta p$ Pressure drop on the nozzle, Pa
- $P$ Power of the burner, kW
- $u_{AV,DIS}$ Average flow rates of fuel/air mixture through the flame ports, m/s
- $u_{FP}$ Flame front propagation rate, m/s
