Abstract: *The paper presents an assessment of the unwanted temperature nonuniformity found in high temperature applications of the pulse calorimetry technique. Specimens in the form of a solid cylinder undergoes fast electrical heating and an intense heat radiation at high temperatures, coupled with the heat conduction to the specimens' cold ends, make them having a highly nonuniform temperature distribution, both in their radial and axial directions. By using FEM simulations of a typical pulse calorimetry experiment, the temperature nonuniformity across the specimen diameter and along the specimen effective length has been estimated for different specimen dimensions and materials, as well as for different heating rates. The obtained results suggest that an optimization of experimental parameters, such as the specimen diameter, specimen total and effective length and heating rate, is needed for minimization of the temperature nonuniformity effect.*

Keywords: *heat conduction; heat radiation; high temperatures; pulse calorimetry; thermophysical properties*

1. INTRODUCTION

The pulse calorimetry technique for the measurement of thermophysical properties of electroconductive materials at high temperatures is well documented in literature. Although a direct electrical heating of specimens in the form of wire or thin rod and a measurement of the related stored energy had been established in 1918 by Worthing [1], an elevated heating rate was applied much later by Nathan [2] in order to reduce heat conduction effects producing a nonuniform temperature distribution along the specimen and possible chemical reactions and mechanical stress of the specimen at high temperatures. This author used the heating rate of 1000 K/s and recorded the transient specimen temperature by a 0.1 mm spot welded Pt/Pt13%Rh thermocouple. The same principle was then applied by Kollie [3], who introduced a fast digital data acquisition system for simultaneous measurement of related experimental signals, while an experimental facility and data reduction based on this work was later used by Dobrosavljević and Maglić [4]. With a development of radiation noncontact thermometry, even faster heating rate was first presented by Cezairliyan et al. [5]. They introduced a high-speed photoelectric pyrometer and a specimen in the form of tube with a tiny centered hole through which radiation passed towards the detector. Assuming a black body radiation from the hole, the recorded radiance temperature was taken as the absolute specimen temperature.

Although the rise of the heating rates minimizes the heat conduction effect, the temperature distribution across the specimen diameter and along the specimen length remains always nonuniform due to inevitable radiation at high temperatures and existing boundary conditions that keep the specimen ends at a low temperature. However, quantitative study of this temperature nonuniformity is

only possible by using some numerical means, such as FEM analysis. Thus, based on the theoretical work of the heat diffusion in presence of electrical current by Bárta [6], first simulations of the pulse heating technique and corresponding analysis of the temperature distribution were made by Spišiak et al. [7]. They considered a tungsten specimen in the form of a thick and long cylinder, assuming a finite temperature gradient across the specimen diameter and zero temperature gradient along the specimen length. By taking tungsten and titanium as examples of high and low thermal conductivity materials, Kaschnitz and Supancic [8] studied temperature distribution in a tubular specimen form with a centered hole, which was used in practice for noncontact temperature measurements. They assessed a temperature nonuniformity across the specimen diameter, but particularly found a significant temperature distortion in the vicinity of the hole. In order to minimize the latter effect, these authors suggested an optimization of both the tube and hole dimensions. The initial work of Spišiak et al. was continued by Bussolino et al. [9], where they applied a numerical model on the cylindrical tungsten specimen, for three different specimen diameters and for a constant specimen length, also under assumption of the temperature uniformity along the specimen length. Later, Bussolino and Righini [10] applied the same model on the tubular specimen, but used two different heating rates and included thermal expansion for the analysis of the temperature distribution, mainly across the specimen.

As the use of solid cylindrical specimens in pulse calorimetry has been recently extended to very high temperatures (Milošević [11]), the study of temperature distribution both across and along the specimen remains open for relatively small heating rates, which is the case in applications with contact temperature measurements, as well as for specific specimen dimensions that may be found in practice, implying relatively thick diameters and small lengths. Moreover, an important temperature gradient may exist in both radial and axial directions of the specimen in the cases of specimen materials with high thermal conductivity and emissivity values. In this work, therefore, the temperature nonuniformity in such the circumstances was computed and analyzed. First, a model that corresponds to boundary and transient conditions similar to those found in practice has been created in COMSOL® Multiphysics software. Then, the model has been validated using the recent high temperature experimental data on a tungsten specimen [11] and, finally, applied for studying the temperature distribution across and along the specimen for different heating rates, specimen diameters and length, as well as for three different materials, tungsten, molybdenum and tantalum. Results of the study are presented and discussed.

2. MODEL AND VERIFICATION

2.1. Model

The principle of the pulse calorimetry technique is as follows: A rod shaped specimen of the material under test is heated by electrical current during a short period of time and let to be freely cooled afterwards. The ends of the specimen are hold at the ambient temperature, T_0 . The transient temperature at the central location of the specimen surface, T_c , is measured by thermocouple or radiation thermometer. Data on the specimen current, i , voltage drop across the specimen effective length, u_{eff} , and temperature of the specimen center, T_c , are simultaneously recorded during the heating and the beginning of the cooling period and subsequently used for the determination of the specimen thermophysical properties, such as the specific heat and specific electrical resistivity.

Mathematical description of this principle is given by the heat diffusion equation in electrical conductors, as [6]

$$\delta c_p \frac{\partial T}{\partial t} = \nabla k \nabla T + \mu j \nabla T + \rho j^2 \quad (1)$$

where T , t , δ , c_p , k and ρ are temperature at any specimen point, time, density, specific heat, thermal conductivity and specific electrical resistivity of the specimen material, while μ and j are the Thomson coefficient and electrical current density through the specimen, respectively. At the beginning of the heating period, the specimen temperature is equal to that of the ambient and at the end of the same period starts the specimen cooling. The boundary conditions at the specimen lateral surface (radial direction, r) is defined by the Fourier and Stefan-Boltzmann law, as

$$-k c_p \frac{\partial T}{\partial r} = \varepsilon_{\text{th}} \sigma (T^4 - T_0^4), \quad r = R \quad (2)$$

where R , ε_{th} and σ are the specimen radius, total hemispherical emissivity of the specimen surface and Stefan-Boltzmann, respectively, while boundary conditions at the specimen two base surfaces (axial direction, x) are those of the first, Dirichlet type, i.e.,

$$T = T_0, \quad x = 0, L \quad (3)$$

where L is the specimen length. Equations (1)-(3) coupled with the Maxwell equations, which describe electrical field and current density, represent the model used in this work.

A model having this principle was created by using the COMSOL® Multiphysics software. The input parameters of the model were the specimen dimensions at ambient temperature, all the related temperature-dependent thermophysical properties of the specimen material (specific heat, thermal conductivity, specific electrical resistivity, total hemispherical emissivity, the coefficient of thermal expansion and density) and the time-dependent DC current which passes through the specimen. On the other hand, application of the model gave the temperature values within the entire specimen volume, voltage drop across the specimen effective length, as well as the specimen length and diameter variation due to the corresponding thermal expansion.

2.2. Verification

In order to verify the model, simulations were performed using the measured data and parameters from a recent experiment made on a pure polycrystalline tungsten specimen [11]. The specimen was 3.43 mm in diameter, 200.7 mm in length and 19.27 g/cm^3 in density. The heating time durations were from 900 ms to 2 s, with the constant time step of 1 ms. As input parameters in simulations, the directly measured data on DC current was used, as well as the following thermophysical properties of tungsten taken from the literature: the specific heat, specific electrical resistivity and total hemispherical emissivity from [11], thermal conductivity from [12] and the coefficient of thermal expansion from [13]. In the same way as in real experiments, the thermal stress of the specimen was simulated by fixing its one end and leaving the rest free to expand in all directions, while the effective specimen length, symmetrically located from the specimen center and over which the voltage drop and temperature distribution were computed, was 20 mm at ambient temperature.

Simulation data and their comparison with typical experimental signals are given in Fig. 1. A good coincidence can be observed, both in the temperature and voltage drop values. Slight difference in data can be seen at higher temperatures only, which is the consequence of using in simulations the averaged functions of the specimen thermophysical properties.

Fig. 1. Comparison between measured and simulated data during the specimen heating: (a) surface temperature of the specimen center and (b) voltage drop across the specimen effective length

As the validity of the model was verified, temperature nonuniformity along and across the specimen could be studied. As an example, using the same input parameters and specimen material, temperature distributions in two directions during the specimen heating are shown in Fig. 2. It can be seen that, in this case, the temperature distribution in axial direction is far more uniform than that in the radial direction, which confirms, in general, the validity of a long wire approximation used in previous studies [7]-[10]. In this work, however, simulations were performed for short and thick specimens and for three different materials and corresponding results are presented in the next section.

3. RESULTS AND DISCUSSION

In order to investigate the temperature distribution in the specimen in both axial and radial directions, simulations have been performed for different heating rates, specimen diameters of 1, 3 and 5 mm, total specimen lengths of 50, 60 and 80 mm and for specimen materials of tungsten, tantalum and molybdenum. The effective specimen length was kept constant at the typical value of 20 mm. As for tungsten in the previous section, input data for tantalum and molybdenum thermophysical properties are taken from literature, as follows: the specific heat, specific electrical resistivity and total hemispherical emissivity from [14] for tantalum and from [15] for molybdenum, while thermal conductivity and the coefficient of thermal expansion from [12] and [13], respectively, for the both materials. The radial temperature nonuniformity, ΔT_{rad} , represented the maximum temperature difference across the central specimen cross-section, while the axial temperature nonuniformity, ΔT_{ax} , implied the maximum temperature difference on the specimen surface along the specimen effective length. For the sake of comparison, only the data of the temperature distribution at 2500 °C were taken for analysis.

Therefore, results of simulations on the temperature nonuniformity across the specimen in function of the heating rate, r , and for three specimen diameters and three specimen materials are given in Fig. 3. It can be seen that for the smallest specimen diameter, the radial temperature nonuniformity is smallest, regardless the heating rate and the specimen material. It increases almost linearly for thicker specimens, but decreases slowly with the heating rate rise. Concerning the material, the radial nonuniformity is highest for tantalum, which is expected as its total hemispherical emissivity is much higher at 2500 °C than that of tungsten and molybdenum. Overall, according to these results, the effect of the radial nonuniformity can be neglected only in thin specimens, which is in agreement

with the previous studies mentioned above, while the influence of the heating rate seems to be not significant for this temperature distribution.

Fig. 3. Temperature nonuniformity across the specimen at 2500 °C in function of the heating rate for different specimen diameters and materials

On the other hand, the results of the temperature nonuniformity along the specimen effective length, also in function of the heating rate and for different specimen diameters, lengths and materials, are shown in Fig. 4. According to them, two first clear outcomes are seen: the axial temperature nonuniformity dramatically rises with the decrease of the total specimen length and the same nonuniformity equally falls with the rise of the heating rate, regardless the specimen diameter and material. The former means the longer the total specimen length, the better the temperature uniformity along the specimen effective length and there is a critical total specimen length, let's say 80 mm in these examples, below which this uniformity dramatically worsens. The other outcome reveals that even in the case of the shortest total length, the axial temperature nonuniformity practically disappears with a sufficient mounting of the heating rate.

The results presented in Fig. 4 also show that the level of axial temperature nonuniformity is influenced by the specimen diameter and material. A lower diameter generally means a better axial uniformity, which, having the same effect on the radial uniformity, completely justifies approximation of a thin and long wire used by the previous authors. For higher diameters, however, the temperature nonuniformity along the specimen effective length may rise significantly, as it is shown in Fig. 4. Concerning the specimen material, the axial temperature nonuniformity is most affected by the material's thermal conductivity and thermal diffusivity. As of three selected materials tungsten has the highest and tantalum the lowest value of thermal conductivity at 2500 °C, so the order of the axial temperature nonuniformity for these three materials is equivalent for the same specimen diameter and the heating rate.

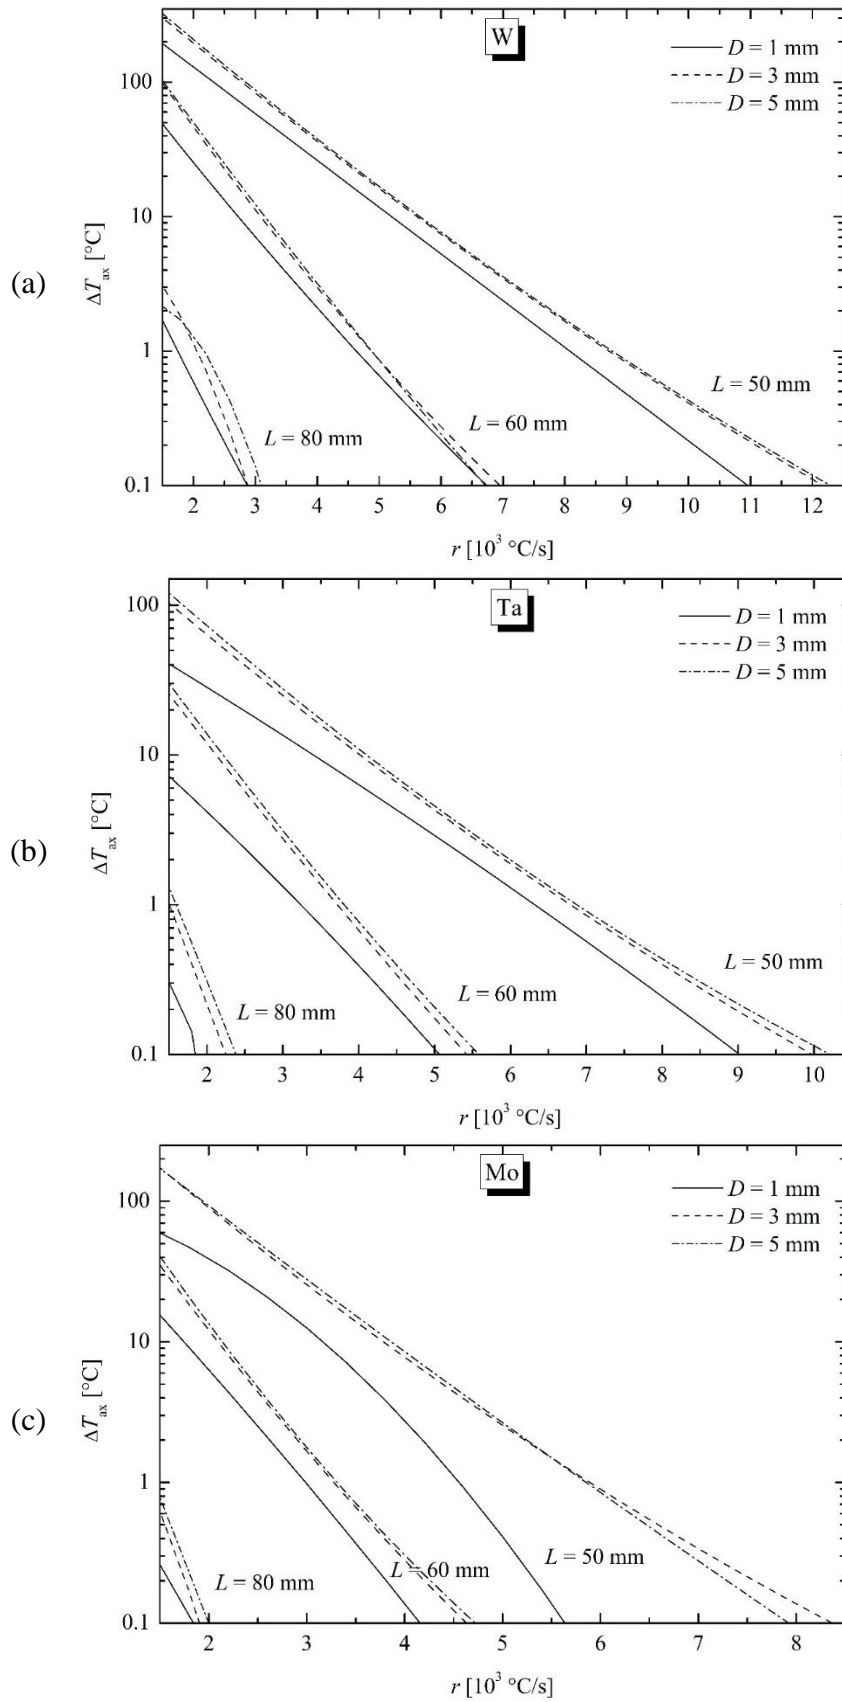

Fig. 4. Temperature nonuniformity along the specimen effective length at 2500 °C and in function of the heating rate and different total specimen lengths and diameters for (a) tungsten; (b) tantalum and (c) molybdenum

All these results, for both the radial and axial temperature distributions, reveal a strong and complex dependency between the temperature nonuniformity during the specimen heating from one side and specimen dimensions, various thermophysical properties of the specimen material and experimental parameters, such as the heating rate and specimen effective length, from the other side. In practice, the properties of the specimen material are normally unknown, need to be determined and cannot be modified. Therefore, in order to minimize the temperature nonuniformity across and along the specimen in the pulse calorimetry technique, the specimen dimensions, heating rate and specimen effective length should be optimized.

An effective approach for this optimization is, certainly, the use of thin and long specimens. However, such the specimens may have too high electrical resistance, which may, in turn, require a high DC power source for heating the specimen rapidly. The same requirement will be in the case of rising the heating rate. Moreover, too high heating rates imply the use of temperature sensors with a very high responsivity, which is difficult to achieve with the contact thermometry. Finally, the specimen effective length may be reduced in order to make the temperature nonuniformity less important, but such a reduction has also limits because it may produce a significant loss of the signal-noise ratio of the voltage drop measurement, as well as an important increase of the uncertainty of the obtained thermophysical properties, specific heat and specific electrical resistivity. Therefore, in each specific application of the pulse calorimetry technique, i.e., for each specimen material and its dimensions and expected properties, one should perform a corresponding simulation, estimate the value of the radial and axial temperature nonuniformity and set the experimental parameters, heating rate and specimen effective length, in order to minimize the effect of the nonuniform temperature distribution on the final measurement results.

CONCLUSION

Standard application of the pulse calorimetry technique assumes conditions of a uniform temperature distribution across the specimen diameter and along the specimen effective length. Such conditions are usually satisfied in practice in the cases of heating thin and long specimens. By using FEM simulations in COMSOL® Multiphysics, the results of virtual experiments reveal that the level of the temperature nonuniformity in both the radial and axial specimen direction for different specimen dimensions and materials, as well as for different heating rates, significantly varies. While the temperature nonuniformity across the specimen diameter linearly increase with the rise of the specimen thickness, the nonuniformity along the specimen effective length may dramatically rise with the decrease of the specimen total length. Also, both the radial and, especially, axial temperature nonuniformity are reduced with the heating rate mounting. Therefore, in order to reduce the effect of a nonuniform temperature distribution for relatively thick and short specimens, it is necessary to perform corresponding numerical analysis and optimize experimental parameters, such as the heating rate and specimen effective length.
