*In this study, the performance of water-based fracturing fluids and supercritical CO<sub>2</sub> in three types of representative reservoirs (sandstone, conglomerate, and shale) was investigated. The results showed that there are differences in fracture initiation pressures in different rocks, but the fracture initiation pressure of supercritical CO<sub>2</sub> is lower than that of water regardless of the rock type. In sandstone reservoirs, supercritical CO<sub>2</sub> induced more complex fractures than water, resulting in branching fractures. In conglomerate reservoirs, hydraulic fractures pass through the conglomerate and are flatter, whereas supercritical CO<sub>2</sub> fractures pass through or around the conglomerate, and thus the fractures are more tortuous. Gravel stopped the fracture extension in both conditions. In shale reservoirs, supercritical CO<sub>2</sub> can communicate natural fractures more effectively than water, thereby increasing the effective transformation volume. The study provides theoretical guidance for reservoir adaptation of supercritical CO<sub>2</sub> fracturing.*

## Introduction

Unconventional oil and gas reservoirs have dense rocks with extremely low porosity and permeability, requiring hydraulic fracturing to construct oil and gas seepage pathways for commercial

development. Water-based fracturing fluids are widely used to crush the reservoir and carry the proppant to form highly conductive fractures. However, there are some shortcomings of water-based fracturing fluids in the application process. Water swells clay minerals and softens the fracture surface, which embeds the proppant and reduces the hydraulic conductivity [1-3]. The water required for hydraulic fracturing wells is measured in tens of thousands of cubic meters, which consumes a large amount of water resources, while the return fluid will pollute the environment.

Supercritical CO<sub>2</sub> attracts attention with its unique physical and chemical properties. It has an extremely low viscosity and a density close to that of water. Supercritical CO<sub>2</sub> replacing water as a fracturing fluid will avoid clay expansion, reduce fracture initiation pressure, and create a complex fracture network in the reservoir [4-6]. Injected CO<sub>2</sub> increases formation pressure and benefits production. In addition, CO<sub>2</sub> can displace adsorbed methane and improve recovery while allowing for carbon sequestration [7]. Numerous experimental and numerical simulation studies have been carried out on CO<sub>2</sub> flow in wells and fractures, fracture initiation and propagation, and proppant transportation [8-12]. Yang Bing *et al.* [13] used CT to reconstruct the fracture in three dimensions and clarified that supercritical CO<sub>2</sub> produces more complex fractures under smaller differential stress. Zhou Dawei *et al.* [14] investigated the temperature effect caused by injected CO<sub>2</sub>, and the results showed that the reduction of effective stress caused by thermal tensile stress and pore pressure is the main reason for the reduction of fracture pressure and the formation of fracture network in supercritical CO<sub>2</sub> fracturing and that the increase of temperature difference between reservoir and injected CO<sub>2</sub> is favorable for fracturing. Wang Haizhu *et al.* [15] established a wellbore flow model for supercritical CO<sub>2</sub> fracturing return flow and found that reducing the discharge volume and increasing the tubing size can effectively keep the wellbore temperature high and reduce the risk of CO<sub>2</sub> hydrate formation. Zheng Yong *et al.* [16] investigated the effect of pump injection schedule on proppant transportation in supercritical CO<sub>2</sub> fracturing by CFD-DEM method and found that injecting high-density proppant first followed by low-density proppant and lowering the initial temperature can improve the performance of supercritical CO<sub>2</sub> carrying proppant.

Nevertheless, the formation adaptability of CO<sub>2</sub> fracturing technology is still unclear. To address this issue, water, and CO<sub>2</sub> fracturing experiments were carried out on three typical reservoir rocks (sandstone, limestone, and conglomerate) in this paper. Characteristics of injection pressure variations were analyzed. The differences between the fracture morphology of water and CO<sub>2</sub> fracturing were compared. The results of the study are a guide to understanding the effectiveness of CO<sub>2</sub> fracturing in reservoirs with different lithologies.

## Materials

To compare the differences between water and CO<sub>2</sub> fracturing in reservoirs with different lithologies, three rocks were selected for this paper. Sandstone and limestone were drilled from natural outcrops extracted from the Ordos Basin. The conglomerate outcrops collapsed after weathering, making it difficult to drill the sample. Therefore, artificial conglomerates cemented with concrete and gravel were taken. A hole with a depth of 55mm was drilled in the center of a  $\phi 50\text{mm} \times 100\text{mm}$  cylindrical sample as a wellbore to inject the fracturing fluid. At the same time, the bottom of the borehole is reserved for a 10mm open hole section, as shown in Figure.1. The experimental scheme is shown in Table 1.

Table 1 experimental design

No.	Rock type	Fluid type	Temperature/°C	$\sigma_v * \sigma_r$ /MPa	InjectionRate/mL·min <sup>-1</sup>
#1	Sandstone	Water	40	5*15	40
#2		CO <sub>2</sub>			
#3	Limestone	Water			
#4		CO <sub>2</sub>			
#5	Conglomerate	Water			
#6		CO <sub>2</sub>			

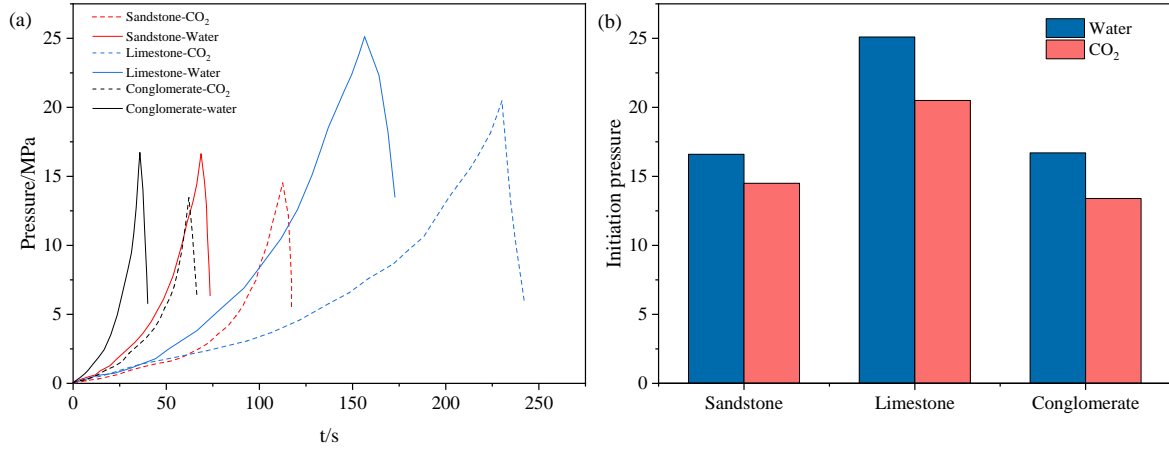

## Apparatus

The fracturing device used is shown in Figure. 2, which can carry out fracturing experiments with a variety of fluids, including water, carbon dioxide, and nitrogen.

The supercritical CO<sub>2</sub> injection device was used by a pneumatic booster pump to pressurize the low-pressure CO<sub>2</sub> and store it in a high-pressure tank. CO<sub>2</sub> is heated by a water bath to bring it to a supercritical state. A maximum pressure of 100MPa is available. The water injection unit provides water injection at a constant rate or pressure by ISCO pumps. The core holder of the confining pressure loading device can contain samples of  $\phi 50\text{mm} \times 100\text{mm}$ , and axial and radial stresses of up to 80MPa could be applied through the hydraulic pump.

## Fracturing evolution characteristics

Figure 3 demonstrates the pressure-time profiles of water- and CO<sub>2</sub>-induced fractures in different rocks. The pressure reached the peak value and then decreased rapidly. The trends of the curves indicated that all three rocks showed strong brittleness during the fluid-driven damage. The pressure profiles have similar characteristics regardless of the rock type. The pressure profile of CO<sub>2</sub> has a smaller slope at the beginning of injection compared to water. The pressure curves have similar characteristics regardless of the rock. The pressure curve of CO<sub>2</sub> has a smaller slope at the early stage of injection compared to water. This is because CO<sub>2</sub> is more strongly compressible than water, and the pressurization process needs to compress the CO<sub>2</sub> first, so the initial pressurization rate is slower. As a result, CO<sub>2</sub>-induced rocks take longer to fracture than water. This also allowed sufficient time for CO<sub>2</sub> to spread through the pores of the rock, increasing the pore pressure and reducing the effective stress.

**Figure. 3 Injection pressure profile (a) and initiation pressure (b)**

CO<sub>2</sub> fracturing has a lower initiation pressure than water in all three rocks. During the fracturing process, the surface tension of the fluid is directly related to whether it can enter the crack tip [17-18]. In the process of fracture propagation, supercritical CO<sub>2</sub>, which has a lower viscosity and almost zero surface tension, has less flow resistance inside the fracture and could reach the fracture tip. As shown in Figure.4, supercritical CO<sub>2</sub> has a smaller fluid lag zone at the crack tip, which reduces the net pressure required for crack propagation [19].

**Figure. 4 Schematic diagram of crack tips for different fluids (a) Water and (b) CO<sub>2</sub>**

Since the rock samples in the experiment were small, crack initiation and extension occurred almost at the same time, and the peak of the pressure curve was assumed to be the initiation pressure, as shown in Figure.3(b). The fracture initiation pressures for CO<sub>2</sub> fracturing in sandstone, chert, and conglomerate were decreased by 2.6 MPa, 4.6 MPa, and 3.1 MPa, respectively. In limestone with high initiation pressure, the effect of CO<sub>2</sub> fracturing in reducing initiation pressure is more significant.

### Fracture morphology

The fracture morphology of water and CO<sub>2</sub> fracturing in different rocks is shown in Figure. 5. It can be visualized that hydraulic fracturing produced only one main fracture and CO<sub>2</sub> fracturing induced a more complex fracture.

In sandstones, hydraulic fracturing produces a relatively simple fracture with only one main fracture perpendicular to the wellbore. In contrast, CO<sub>2</sub>-induced fractures have complex geometries. The fractures produced branches and secondary fractures after fracture initiation at the bottom of the wellbore. Due to the presence of laminations in the sandstone, the fracture morphology is also influenced by the laminations. In limestones, hydraulic fracturing produced a main fracture that intersected the wellbore diagonally. The fracture was deflected along the axial stress after initiating from the bottom of the borehole. In addition to the near wellbore, CO<sub>2</sub> fracturing produced a fracture in the lower portion of the rock sample and a partial collapse on the side of the sample.

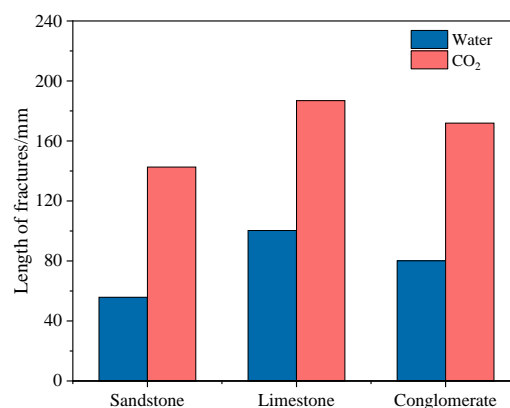

The presence of conglomerates gives conglomerates a stronger heterogeneity than sandstones and limestones. The strength of the gravel, its content, its size, and cementation strength all affect the

final patterns of the cracks[20-21]. Four modes of fracture-gravel interaction exist: penetration, deflection, attraction, and termination[22]. Penetration and deflection occurred in hydraulic fracturing, and deflection and attraction occurred in CO<sub>2</sub> fracturing in this study. Fractures in conglomerates were significantly more tortuous than in sandstones and limestones. Most of the CO<sub>2</sub>-induced fractures in conglomerates are deflections rather than penetrations. It is explained by the fact that CO<sub>2</sub> has a much lower viscosity and can enter the interface between the conglomerate and the matrix. And it is easier to open the interface than to crush the matrix and gravel. Moreover, matrix collapse can be seen near the gravels in the CO<sub>2</sub>-fractured rock samples. These disintegrated particles can act as proppants to form self-supporting fractures.

**Figure. 5 Fracture morphology of water and CO<sub>2</sub> fracturing in different rocks**

The lengths of water- and CO<sub>2</sub>-induced fractures in three rocks were counted, as shown in Fig.6. CO<sub>2</sub> fracturing forms multiple fractures, so the fracture lengths are significantly longer than those of hydraulic fracturing. The lengths of CO<sub>2</sub>-induced fractures in sandstone, limestone, and conglomerate were 2.56, 1.86, and 2.15 times the lengths of those induced by water, respectively.

**Figure. 6 Length of fractures induced by water and CO<sub>2</sub> fracturing in different rocks**

## Conclusion

Several important conclusions can be drawn from the current experimental studies of hydraulic fracturing performed by injecting water and CO<sub>2</sub> into different rocks: CO<sub>2</sub> could reduce the initiation pressure of rock, and this effect is more pronounced in dense and stiff reservoirs. The initiation pressure of CO<sub>2</sub> fracturing in limestone was 4.6 MPa lower than that of water. For different rocks, CO<sub>2</sub> fracturing produces more tortuous fractures with more complex spatial patterns, which provide more efficient flow channels for oil and gas transportation. Enhancement of CO<sub>2</sub> fracturing in conglomerate reservoirs is more pronounced than in sandstones and limestones. In dense, hard, heterogeneous water-

sensitive reservoirs, CO<sub>2</sub> is more preferred than water as a fracturing fluid. The results of the study provide a reference for the selection of fracturing fluids for reservoirs with different lithologies. In reservoirs with a high content of carbonate minerals, the dissolving effect of CO<sub>2</sub> on minerals cannot be neglected, which needs further study.
